(February 8, 2008)

Abstract

A supersymmetric inversion method is applied to the singlet 1S_0 and 1P_1 neutron-proton elastic phase shifts. The resulting central potential has a one-pion-exchange (OPE) long-range behavior and a parity-independent short-range part; it fits inverted data well. Adding a regularized OPE tensor term also allows the reproduction of the triplet 3P_0 , 3P_1 and 3S_1 phase shifts as well as of the deuteron binding energy. The potential is thus also spin-independent (except for the OPE part) and contains no spin-orbit term. These important simplifications of the neutron-proton interaction are shown to be possible only if the potential possesses Pauli forbidden bound states, as proposed in the Moscow nucleon-nucleon model.

Although of fundamental importance for the whole field of nuclear physics and despite 70 years of intensive research, a definitive form for the nucleon-nucleon interaction has not yet been established. Since an individual nucleon is made up of three quarks, this interaction should in principle be deduced from an *ab initio* quantum chromodynamics description of a six-quark system. However, such a six-body highly-relativistic problem is out of reach of our present calculation capacities. Hence, *phenomenological* interactions, i.e., interactions constructed to reproduce nucleon-nucleon experimental data (deuteron bound state and scattering cross sections) have to be constructed. These interactions may be divided in two categories.

The first category is based on the theoretical framework of meson exchange and fulfills the symmetries of the system. The best known are the Paris [1], Nijmegen [2], Bonn [3], and Argonne [4] interactions. All these models agree on the long-range part of the interaction ($r > 3$ fm, where r is the inter-nucleon distance): it is well described by a central (C) and a tensor (T) one-pion-exchange (OPE) potential. Both terms depend on the total spin S and parity π of the nucleon-nucleon system. The whole potential reads

$$V = V^{\text{s.r.}} + V_{\text{C}}^{\text{OPE}}(S, \pi) + V_{\text{T}}^{\text{OPE}}(S, \pi), \quad (1)$$

where the short-range part $V^{\text{s.r.}}$ follows from the exchange of other mesons and from a purely phenomenological contribution. Its precise form differs from model to model but it at least contains a central, a tensor, a spin-orbit (SO), and a quadratic spin-orbit (QSO) term,

$$V^{\text{s.r.}} = V_{\text{C}}^{\text{s.r.}}(E_{\text{c.m.}}, S, \pi) + V_{\text{T}}^{\text{s.r.}}(S, \pi) + V_{\text{SO}}^{\text{s.r.}}(S, \pi) + V_{\text{QSO}}^{\text{s.r.}}(S, \pi), \quad (2)$$

all depending on spin and parity. The central-part dependence on the center-of-mass energy $E_{\text{c.m.}}$ makes the potential non local.

The second category of interactions is physically less justified: the long-range part is also described by the OPE potential while the short-range part has a simpler but more phenomenological structure. In the Reid potential [5], $V^{\text{s.r.}}$ has neither QSO term nor energy dependence. The price to pay for this simplification is a partial-wave dependence of the potential: instead of a dependence on S and π , it depends on S and on the orbital and total angular momenta L and J . There is thus an implicit non-locality and this interaction does not fulfill the symmetries of the system. An even simpler form is proposed in the latest version of the Moscow model [6]. In this case, the short-range potential consists of a local part only depending on spin and parity, without tensor term,

$$V_{\text{local}}^{\text{s.r.}} = V_{\text{C}}^{\text{s.r.}}(S, \pi) + V_{\text{SO}}^{\text{s.r.}}(S, \pi), \quad (3)$$

and a non-local separable term depending on the partial wave $V_{\text{sep}}^{\text{s.r.}}(S, L, J)$. This further simplification of the interaction structure is made possible by the introduction of Pauli forbidden bound states (PFSs) in the lowest partial waves. These non-physical states are

aiming to simulate the Pauli exclusion principle between the six quarks constituting the interacting nucleons [7]. Their presence results in a *deep* potential without repulsive core, whereas other nucleon-nucleon interactions, which only possess *one* physical bound state (the deuteron), are *shallow* and present a repulsive core below about 1 fm.

In the present work, we show that the use of a deep potential allows a further simplification of the short-range local part (3). Neither the spin and parity dependence nor the spin-orbit term seem to be necessary to fit data, so that one only has

$$V_{\text{local}}^{\text{s.r.}} = V_{\text{C}}^{\text{s.r.}}. \quad (4)$$

Spin and parity dependences, or equivalently spin-spin and isospin-isospin terms, are generally considered as essential ingredients of the nucleon-nucleon interaction, in contrast with Eq. (4). Besides the presence of PFSs, the present simplification requires a more complicated central part than in the Moscow model, where an exponential or Gaussian form factor is assumed from the beginning. Here we deduce this form factor from neutron-proton scattering data through the use of the supersymmetric inversion method of Ref. [8]. This technique allows the construction of a partial-wave-independent potential from elastic scattering phase shifts of several partial waves. In Ref. [8], the inversion method is applied to the system of two α particles, for which the inclusion of PFSs has been known to considerably simplify the interaction for a long time. We show here that a similar simplification occurs in the interaction between two nucleons, a fact ignored up to now.

Our inversion method is a two-step procedure [8]. We first invert the phase shifts $\delta(k)$ of the singlet ($S = 0$) 1P_1 partial wave. As “experimental” data we use the multienergy phase shifts PWA93 of Ref. [9] at $E_{\text{c.m.}} = 0.05, 0.5, 2.5, 5, 10, 15, \dots, 140$ MeV (below the inelastic pion-production threshold). The wave number k (in fm^{-1}) is related to $E_{\text{c.m.}}$ (in MeV) through $k = \sqrt{2\mu E_{\text{c.m.}}/\hbar^2}$, where $\mu = 469.45926$ MeV/ c^2 is the neutron-proton reduced mass with $\hbar c = 197.327053$ MeV fm. We use a rational approximation of the scattering S -matrix

$$S(k) \equiv e^{2i\delta(k)} \approx S_{\text{C}}^{\text{OPE}}(k) \prod_{m=1}^M \frac{\kappa_m + k}{\kappa_m - k}, \quad (5)$$

where $S_{\text{C}}^{\text{OPE}}$ is the S -matrix of $V_{\text{C}}^{\text{OPE}}$ ($V_{\text{T}}^{\text{OPE}}$ vanishes for singlet waves) and κ_m are complex wave numbers fitted to experimental data. Potential $V_{\text{C}}^{\text{OPE}}$ depends on spin and parity through the spin and isospin Pauli matrices of the nucleons $\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2, \boldsymbol{\tau}_1, \boldsymbol{\tau}_2$. It reads (in MeV)

$$V_{\text{C}}^{\text{OPE}}(S, \pi, r) = \frac{\boldsymbol{\tau}_1 \cdot \boldsymbol{\tau}_2}{3} 0.075 m_{\pi} c^2 \Phi_{\text{C}}^0(r) (\boldsymbol{\sigma}_1 \cdot \boldsymbol{\sigma}_2), \quad (6)$$

where an averaged pion mass $m_{\pi} = 138.0363$ MeV/ c^2 has been used (distinguishing between neutral- and charged-pion exchange does not qualitatively modify the present results). A dipole-regularized form factor Φ_{C}^0 is used [Eq. (9) of Ref. [2]] with a cutoff parameter Λ_{C} given below. Other form-factor choices (as in Ref. [6]) will be discussed elsewhere. For the 1P_1 partial wave, one has $\boldsymbol{\tau}_1 \cdot \boldsymbol{\tau}_2 = \boldsymbol{\sigma}_1 \cdot \boldsymbol{\sigma}_2 = -3$ in Eq. (6). The corresponding OPE phase shifts are represented by a dotted line in Fig. 1. They are satisfactory at low energy only. With three additional S -matrix poles [$M = 3$ in Eq. (5)] located at $\kappa_m = \pm 1.848 + 1.860i$

and $-1.848i \text{ fm}^{-1}$, a perfect data fit is obtained on the whole energy range (upper dashed line in Fig. 1). The values of the poles have been calculated with the method presented in Ref. [10].

The potential corresponding to the rational S -matrix (5) is a generalized Bargmann potential [11]. It may be constructed by three successive supersymmetric transformations [12] of the 1P_1 radial Schrödinger equation with the OPE potential. It has no bound state and is purely repulsive (upper dashed line in Fig. 2) in agreement with traditional shallow nucleon-nucleon interactions. To calculate 1S_0 phase shifts, we modify the OPE term with $\tau_1 \cdot \tau_2 = 1$ instead of -3 in Eq. (6) and we keep the same short-range part [Eqs. (1) and (4)]. This makes the central potential slightly attractive above 1.5 fm (lower dashed line in Fig. 2). However, the repulsive $V_C^{\text{s.r.}}$ dominates and the 1S_0 phase shifts are negative (lower dashed line in Fig. 1), in disagreement with experimental data. Modifying Λ_C does not solve the problem. This explains why shallow nucleon-nucleon potentials always have a strong parity dependence: a shallow potential is unable to fit both the 1S_0 and 1P_1 phase shifts simultaneously.

Let us now perform the second step of our inversion technique [8], namely, the addition of a Pauli forbidden bound state to the 1P_1 effective potential just obtained, in order to construct a deep potential. Such an addition may be done without modifying the 1P_1 phase shifts (phase-equivalent addition) with the help of two successive supersymmetric transformations [13]. Both steps of the inversion method are thus performed with the same algebraic formalism of supersymmetric transformations. Let us define the mean radius $r_{\text{PFS}}^{\text{mean}}$ of the added PFS by

$$\int_{r_{\text{PFS}}^{\text{mean}}}^{\infty} |\psi_{\text{PFS}}(r)|^2 dr = \frac{1}{2}, \quad (7)$$

where ψ_{PFS} is the PFS normalized wave function. An important feature of the phase-equivalent PFS addition is that both the binding energy E_{PFS} and $r_{\text{PFS}}^{\text{mean}}$ may be chosen arbitrarily. Here we choose them to fit the 1S_0 phase shifts together with the 1P_1 ones. However, the obtained central potential has a singular r^{-2} attractive core at the origin and cannot be used as such to estimate 1S_0 phase shifts. Hence we regularize it as $V_{\text{reg}} + ar^2 + br^3$ below a regularization radius r_{reg} , as in Ref. [8]. This only slightly affects the 1P_1 phase shifts provided r_{reg} is lower than the classical turning point for this partial wave at the highest considered energy.

For $E_{\text{PFS}} = -101.9 \text{ MeV}$, $r_{\text{PFS}}^{\text{mean}} = 0.6064 \text{ fm}$, $V_{\text{reg}} = -2071 \text{ MeV}$, $r_{\text{reg}} = 0.8231 \text{ fm}$ and $\Lambda_C = 468.1 \text{ MeV}/\hbar c$, we get a very good fit of the 1S_0 and 1P_1 phase shifts (solid lines in Fig. 1), with root-mean-square (rms) deviations of 3.9 and $2.3 \times 10^{-3}\pi$ respectively. The corresponding central potentials are deep and have no repulsive core. They are represented by solid lines in Fig. 2, together with the energy and mean radius of their PFSs. Let us recall that, by construction, the s.r. term of the potential is parity independent since it fits both an odd (1P_1) and an even (1S_0) wave. Thanks to the soft cutoff parameter, the OPE term only introduces a small parity dependence. Such a soft cutoff is shown to be very satisfactory in Ref. [6] and seems to be a constant feature of deep potentials.

In Fig. 3, we compare the form factor of our potential (solid line) with that of the local part of the Moscow potential [6] (dashed line) for the 1S_0 partial wave. Both potentials have an OPE tail (dotted line) but have different short-range behaviors. In the Moscow model, an

exponential form factor is used, while the inversion potential has a more complicated form factor, which could not have been easily guessed from phase shifts. The inversion potential has no compact analytical expression but it is reasonably well approximated by a sum of two Gaussians

$$V_C^{\text{s.r.}}(r) = -3050 e^{-5.890r^2} - 70.39 e^{-0.5687r^2} \quad (8)$$

(in MeV, r in fm), as shown by the dash-dotted line in Fig. 3. Adding an OPE term with $\Lambda_C = 406.2 \text{ MeV}/\hbar c$ to potential (8) provides rms deviations of 9.3 and $2.4 \times 10^{-3}\pi$ for the 1S_0 and 1P_1 phase shifts respectively, which is still in good agreement with experimental data. In the following, we only use the numerical inversion potential but we have checked that our conclusions also hold for the analytical potential (8), which is of easier use for practical applications.

Let us now show that the inversion potential is also able to fit triplet ($S = 1$) partial waves, in particular the deuteron bound state in the 3S_1 - 3D_1 coupled waves. We have found that it is sufficient to add a tensor OPE term to the above central potential to reproduce the experimental deuteron binding energy $E_d = -2.224575(9) \text{ MeV}$ as well as the 3S_1 phase shifts (Fig. 4) with an rms deviation of $6.0 \times 10^{-3}\pi$. A dipole-regularized form factor Φ_T^0 [Eq. (12) of Ref. [2]] is used with a smooth cutoff parameter $\Lambda_T^{\text{even}} = 601.14 \text{ MeV}/\hbar c$. The deuteron wave function is then similar to that of the Moscow potential (Fig. 5 of Ref. [6]) and has a node in the S wave. The triplet-odd 3P_0 and 3P_1 phase shifts are also reproduced (Fig. 4, rms deviations of 1.3 and $0.9 \times 10^{-3}\pi$ respectively) with a cutoff parameter $\Lambda_T^{\text{odd}} = 517.7 \text{ MeV}/\hbar c$. Finally, the mixing parameters have a good qualitative behavior but ϵ_1 , ϵ_2 and ϵ_3 are too small; this indicates that the tensor form factor could be slightly improved.

The parity-independent central potential deduced from inversion of singlet-even and singlet-odd phase shifts is thus also valid for triplet-even and triplet-odd partial waves. Hence in addition to the parity, it is independent of the spin. To our knowledge, the present potential is the simplest phenomenological model of the nucleon-nucleon interaction able to fit all the above phase shifts simultaneously. Let us insist on the fact that the potential is purely local (no energy dependence, no J or L dependence) and has no spin-orbit term. The potential of Ref. [6], on the contrary, has a spin-orbit and a non-local term for the 3P_0 and 3P_1 waves. Moreover, it has no PFS for these waves, whereas our potential has one PFS for all S and P waves. The present model has thus a simpler structure.

However, our potential does not reproduce the phase shifts of every higher partial waves ($J \geq 2$), which means that the present work is only a first step toward a simpler nucleon-nucleon interaction. In particular, we get negative 3P_2 phase shifts whereas the Moscow model agrees with the positive experimental values. Moreover, the D and F phase shifts have a satisfactory low-energy behavior but are too large at higher energies, as illustrated for instance in Fig. 5 (solid lines) for the singlet partial waves. A similar result is obtained for triplet waves. The higher partial waves ($G, H, \dots$) are well reproduced because they mainly depend on the OPE tail of the potential. The discrepancy for the D and F waves is also encountered with the local part (3) of the Moscow potential (dashed lines in Fig. 5). In Ref. [6], this is solved by the introduction of a repulsive pseudo-potential term $V_{\text{sep}}^{\text{s.r.}}$ for these partial waves. More conventional non-local terms, such as an energy-dependent central part, could also be used and the possibility of a spin- and parity-independent non-local term could be considered.

As a conclusion, this work gives some hope for an important simplification of the phenomenological nucleon-nucleon interaction. A satisfactory local part has been found, which consists of a deep short-range central potential, independent of both spin and parity, and a regularized OPE potential (central and tensor terms). A spin-orbit term does not seem to be necessary, while the question of a satisfactory non-local term is still open. We plan to apply the same technique to proton-proton data (the Coulomb interaction does not complicate the inversion method [10]) in order to study the charge dependence of our model. We would also like to generalize the present inversion technique to the coupled-channel case, which would allow a deduction of the tensor form factor from experimental data. First steps in this direction have already been made [14,15].

I thank Profs. V. I. Kukulin and V. N. Pomerantsev for information on their OPE form factor, as well as Prof. D. Baye for his careful reading of the manuscript and stimulating discussions. I am supported by the National Fund for Scientific Research, Belgium. This text presents research results of the Belgian program P4/18 on inter-university attraction poles initiated by the Belgian-state Federal Services for Scientific, Technical and Cultural Affairs.

FIG. 1. Neutron-proton 1S_0 and 1P_1 phase shifts: data from Ref. [9] (crosses), shallow- (dashed lines) and deep-potential (solid lines) calculations. The 1P_1 phase shifts of both potentials are almost indistinguishable. The 1P_1 phase shifts of the OPE potential (6) for $\Lambda_C = 468.1 \text{ MeV}/\hbar c$ (dotted line) are also shown.

FIG. 2. Shallow (dashed lines) and deep (solid lines) central potentials obtained by supersymmetric inversion for the 1S_0 and 1P_1 partial waves. The 1S_0 and 1P_1 potentials are almost indistinguishable in the left panel, where the energy (horizontal lines) and mean radius (vertical lines) of the deep-potential PFSs are also shown for both partial waves.

FIG. 3. Central potentials for the 1S_0 partial wave: dipole-regularized OPE potential (6) with $\Lambda_C = 468.1 \text{ MeV}/\hbar c$ (dotted line), deep inversion potential (solid line), deep Moscow potential of Ref. [6] (dashed line), sum of the analytical s.r. potential (8) and of the OPE potential (6) with $\Lambda_C = 406.2 \text{ MeV}/\hbar c$ (dash-dotted line).

FIG. 4. Neutron-proton 3S_1 , 3P_0 and 3P_1 phase shifts: data from Ref. [9] (crosses) and calculations (solid lines) with the central inversion potential and an OPE tensor term.

FIG. 5. Neutron-proton singlet phase shifts: data from Ref. [9] (crosses), calculations with the inversion potential (solid lines) and with the local part (3) of the potential of Ref. [6] (dashed lines).
